## Abstract

Based on earlier models developed for polyaddition of diisocyanates and polyols, a non-stoichiometric process was provided for step-by-step polymerisation of 2,4- and 2,6-tolylene diisocyanate (TDI) with diols which had various molecule sizes and the nature of polyethers and polyesters. Said process yielded urethane oligomers which had –NCO or –OH groups as their chain end groups. After elimination of excess monomer, these compounds were—at subsequent stages (2–5)—subjected to further reaction with diisocyanate or with selected polyol. The process was operated in bulk and excess monomers were eliminated with the use of the selective extraction method. Linear products were obtained in that way which had well defined chain structures and narrow distribution of their molecular weights (MWD)  $PD = \bar{M}_w/\bar{M}_n = 1.1–1.3$ . On the basis of IR and mass spectrometry (MS) (electrospray ionization (ESI) and matrix-assisted laser desorption ionization-time of flight (MALDI-TOF)) structural analyses, the expected structures of oligomers were confirmed and the actual compositions of polyurethane mixtures formed at every stage of the polymerisation process could be verified against the data obtained from the model, from the balance calculations (based on determinations of free isocyanate groups) and from the findings of the gel-permeation chromatography (GPC) analysis. Applicability of the presented method was demonstrated and the general scheme was suggested for the process discussed.

## 1. Introduction

Some special applications of polyurethanes (PUs), like membranes, coatings which are biocompatible with living tissues and body fluids (e.g. blood) [1,2], liquid crystal mesogenes with non-linear optical properties [3,4], coatings which are modified by covering them with orderly organic mono- and multi-layers [5], and/or waterborne emulsions and dispersions which incorporate polyacrylates and which have the structures similar to those of interpenetrating polymer networks (IPNs) [6,7], require more and more frequently a precisely defined chemical composition and a narrow distribution of molecular weights, both for intermediates and for polyurethanes to be employed in the manufacturing processes. An interesting example for such an application is the synthesis of urethane–vinyl copoly-

mers by the controlled/living radical polymerisation (CRP) method with the use of urethane macro-initiators [8].

It is a relatively difficult task to manufacture products with controlled chemical compositions and narrow MWDs in case of polymers obtained from the step-by-step polymerisation methods. That effect becomes available in chain growth polymerisation processes when the living ion polymerisation method or one of CRP methods (NMP or ATRP) is employed [9]. The progress in step-by-step polymerisation, which is based on the reaction of functional groups in monomers and on converting said monomers into bigger and bigger oligomers and polymers, can be controlled only to some extent by means of the initial molar ratio of functional groups. It is known on the grounds of Flory's theory that the equimolar ratio of functional groups is favourable for the formation of high-molecular-weight polyaddition products, while the polymer so produced will have a considerably high polydispersity  $PD = \bar{M}_w/\bar{M}_n \gg 3.0$  at the same time [10]. Our earlier reports demonstrated that the ratio PD could be

113 reduced by running a non-stoichiometric polyaddition  
 114 reaction of diisocyanate and polyol with considerable  
 115 excess of one of monomers. However, unconverted excess  
 116 of that raw material needs to be separated (eliminated) after  
 117 every process stage. Yet, the formal polymerisation degree  
 118 DP of the polymer formed at every stage does not exceed 3  
 119 then [11,12]. The question arises if that method could be  
 120 employed to produce linear PUs with well-defined and  
 121 repeatable chemical structures, and what impact can be  
 122 expected from that structure on the arrangements of chains  
 123 within the supermolecular structures, i.e. segments respon-  
 124 sible for the flexible and rigid phases of that polyurethane?  
 125 The generated phase structure is known to be decisive for  
 126 the physical–mechanical properties of PU plastics. At the  
 127 early stage, we tried to find the answer to the above question  
 128 by synthesizing oligourethanes with various molecular  
 129 weights in the reaction of 2,4-TDI and 2,6-TDI (TDI)  
 130 with butane-1,4-diol (BD). The reactions were proceeding  
 131 in tetrahydrofuran (THF); the solvent was used to control  
 132 viscosity of the system [11]. Our another study covered  
 133 numerous stages of the synthesis which was carried out in  
 134 bulk only and which employed—in addition to BD—also  
 135 poly(oxyethylene)glycols (POGs) with  $\bar{M}_n = 200, 400, 600$   
 136 and  $1000$  g/mol [12].

137 Having in mind that the supermolecular structures of  
 138 linear oligourethanes are influenced by the presence of  
 139 intermolecular hydrogen bonds which are much more  
 140 numerous in the segments formed with the participation of  
 141 polyesters than in polyether–urethane segments, it seemed  
 142 justifiable not only using POGs but also polyester–polyols  
 143 and [13,14]. We decided to utilise polycaprolactone diols  
 144 (PCDs) with  $\bar{M}_n = 530$  and  $1250$  g/mol.

145 This report presents the findings from our investi-  
 146 gations. Theoretical grounds have been provided for the  
 147 polyaddition method adopted in the study, the developed  
 148 ways of producing urethane oligomers with precisely  
 149 defined compositions and structures have been described,  
 150 and the findings from structural analyses have been  
 151 shown.

## 152 2. Concept for the step-by-step polyaddition process

153  
 154  
 155  
 156 The model of the stipulated step-by-step polyaddition  
 157 process was based on the controlled synthesis procedure that  
 158 made use of the kinetic model developed for a series of  
 159 successive-parallel reactions. The scheme was just an  
 160 expansion of a generally known equation describing the  
 161 process which yields linear PUs:

164  
 165  
 166  
 167 where  $\text{R}_1$  is the aliphatic or aromatic moiety derived from  
 168 low-molecular-weight diol, polyether–diol or polyester–

169 diol and  $\text{R}_2$  is the aliphatic, aromatic or alicyclic moiety in  
 170 diisocyanate.

171 The process considered can be presented as a train of  
 172 successive-parallel irreversible reactions:

175  
 176  
 177 wherein each reaction has its specific rate constant  $k_i$ . In this  
 178 scheme: A stands for BD, POG or PCD; B is one of TDI  
 179 isomers;  $\text{A}_n\text{B}_m$ , the corresponding oligourethane which can  
 180 be urethane diol  $\text{A}_{n+1}\text{B}_n$  or urethane–diisocyanate  $\text{A}_n\text{B}_{n+1}$ .  
 181 Oligourethane, which is a product of one or a series of a few  
 182 reactions, makes a substrate for some subsequent stage and  
 183 reacts with a monomer, A or B, then.

184 In the beginning, we utilised kinetic models that were  
 185 developed earlier, for numerical simulations of the  
 186 planned processes; the use of different diisocyanates  
 187 and polyols was assumed [15–17]. The simulation  
 188 procedures made it possible to calculate changes in  
 189 concentrations of reacting substances during the process  
 190 as well as the number-average molecular weight of PUs  
 191 in relation to the reaction conditions adopted, i.e. molar  
 192 ratio of functional groups, molecular weight of polyol,  
 193 and temperature, which was represented with the rate  
 194 constant  $k_1$  for reaction 1 in scheme (2) utilised in  
 195 calculations. The developed procedures made it also  
 196 possible to adjust for changing reactivity of diisocyanate.  
 197 The so-called substitution effect could thus be considered  
 198 which is responsible for declining reactivity of the  
 199 second –NCO group in an aromatic diisocyanate, e.g. in  
 200 2,6-TDI, after its first group has been converted into a  
 201 corresponding carbamate structure [17].

202 Fig. 1 shows the examples of calculated molecular  
 203 weights for oligourethanes at successive stages of  
 204 equimolar ( $r = 1$ ) polyaddition of 2,4-TDI and 2,6-TDI

Fig. 2. Molecular weight ( $\bar{M}_n$ ) of PU in relation to the number of the step/stage in polyaddition of TDI to POG-200 ( $k_1 = 0.0005 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ,  $r = 4$ ).

with 1,4-BD, in relation to the value of  $k_1$ . Fig. 2 shows the simulation results for the urethane oligomers production process which has been based on the reaction of TDI and POG 200, with the reaction proceeding with no external catalyst at about 55 °C. The simulation was limited to cover 5–6 stages which were then implemented in practice [18]. The calculation results were helpful in designing a multi-stage method for the synthesis of urethane oligomers.

### 3. Experimental

#### 3.1. Raw materials and reagents

- 2,4- and 2,6-Tolylene diisocyanate (TDI). A commercial product was used in the study. It was a mixture of 2,4-TDI and 2,6-TDI isomers at the ratio of 80 and 20%, respectively, from Aldrich.
- Polyoxyethylene glycol (POG) with  $\bar{M}_n = 200, 300, 400, 600$  and  $1000 \text{ g/mol}$ , from Aldrich. The glycols were dried under vacuum in  $\text{N}_2$ , at temp. 110 °C, during 2 h.
- Polycaprolactone diol (PCD) with  $\bar{M}_n = 530$  and  $1250$ , from Aldrich.
- Benzoyl chloride (pure), from POCh-Gliwice, Poland.
- 1,4-Butanediol (BD) (pure), from Aldrich.
- The solvents: hexane, ethyl acetate, toluene, xylene, carbon tetrachloride, and tetrahydrofuran were reagent grade materials, supplied by POCh-Gliwice, Poland.

#### 3.2. Method for the synthesis of urethane oligomers

The reactions were carried out in bulk in a glass reactor, under nitrogen. Benzoyl chloride was used (0.3 wt% with respect to TDI) as a viscosity control agent; moreover, its use made it possible to expand the stability period of synthesised prepolymers  $A_n B_{n+1}$  and hence the prepolymers could be employed as parent substances in subsequent reactions. The polyaddition process was always initiated by

a reaction which proceeded at a considerable excess of diisocyanate (B). In order to make the complete conversion possible for the parent substances A or B which were in short supply, each reaction - what can be observed in diagram (2)—was carried out at 100% excess of the other reacting substance—BD, POG, PCD or TDI. The feeds were introduced under possibly mild conditions to avoid any uncontrolled conversion of –NCO groups which were still present in the system to allophanates or their cyclisation to isocyanurates. No external catalyst was employed in our experiments. A calculated amount of hydroxyl-terminated or isocyanate-terminated oligomer prepared at an earlier stage was introduced dropwise to TDI or to appropriate glycol, respectively. It was always the minor component that was introduced to the component which was present in excess. The time of introduction was adjusted to last ca. 30 min. The reacting mixture was maintained at  $65 \pm 1^\circ\text{C}$ . The temperature was kept at that level for another 2 h after the predefined volume of the minority component had been added. Extraction was employed to remove excess unconverted monomer after every stage and thus purified intermediate  $A_nB_m$  could be employed as a parent substance for another polyaddition stage.

The principal reactions for every stage I–V are presented in Table 1. The letter a denotes the samples taken directly from the reactor, while the letter b denotes the products after extracting out the excess of TDI or diol.

On the basis of assumed reaction stoichiometry and experimentally determined content of free –NCO groups we could calculate the compositions of initial mixtures, i.e. weight fractions for substrates ( $A_nB_{n+1}$  and B at odd stages 1, 3, 5, as well as  $A_{n+1}B_n$  and A at even stages 2 and 4 of the processes) and for reaction products. In case of even stages

2 and 4, the course of reaction—which conformed to our expectations—and hence the expected chemical compositions of the urethane–hydroxyl oligomers formed was confirmed indirectly by comparing the theoretical and experimental losses in weight for samples after excess monomer A had been extracted out of them.

Exemplary compositions of mixtures at successive stages of the reaction between BD and TDI are shown diagrammatically in Fig. 3.

### 3.3. Example I—synthesis of urethane oligomers from TDI and BD

*I stage.* In a 1 dm<sup>3</sup> jacketed glass reactor fitted with reflux condenser, stirrer and nitrogen inlet tube TDI (696.68 g, 4 M) and benzoyl chloride (2.09 g, 0.3 wt%) was charged. After heating the reaction mixture to  $65 \pm 1^\circ\text{C}$ , BD (90.00 g, 1 M) was added drop by drop in the time of 30 min. Then the heating was continued 2 h in order to supply total BD conversion. After the end of the reaction, precipitate of the product (I-BDa) was washed by the mixture *n*-hexane and ethyl acetate equal 2:1. The concentration of –NCO groups after the end of extraction amount 36.32% (theoretically: 39.43%). The obtained product I-BDb was dried under a vacuum in the time of 15 min and then used as a substrate in the next stage.

*II stage.* In a 1 dm<sup>3</sup> jacketed glass reactor BD (300.29 g, 3.34 M) and benzoyl chloride (0.12 g, 0.3 wt% to I-BDb). After heating the reaction mixture to  $65 \pm 1^\circ\text{C}$ , I-BDb (400.00 g, 0.834 M) was added drop by drop in the time of 30 min. Then, heating was continued 2 h. The obtained product (II-BDa) was in the form of very sticky liquid. Very little amount of THF was added to it in order to make the

561 extraction easier. Unreacted excess of BD was extracted by.  
 562 The extraction was carried out to get constant weight of the  
 563 sample according to theoretical dates (580.00 g; 0.834 M).  
 564 At the end of the extraction, the product was dried under a  
 565 vacuum at 90 °C in 15 min. The product II-BDb was a hard  
 566 and transparent resin.

567 *III stage.* The reaction was carried out analogous to the I  
 568 stage 300.00 g (0.50 M) II-BDb and 348.34 g (2.00 M) TDI  
 569 were used. The concentration of the –NCO groups in the  
 570 final product after extraction (III-BDb) amounted to 14.28%  
 571 (theoretically: 17.28%).

572 *IV stage.* The reaction was carried out analogous to the II  
 573 stage. 300.00 g (0.246 M) III-BDb and 88.55 g (0.984 M)  
 574 BD were used. The extraction was carried out by water till  
 575 constant weight 344.27 g (0.246 M) of the product (V-  
 576 BDb).

577 *V stage.* Analogous to the I or III stage.

### 579 3.4. Example II—synthesis of urethane oligomers from TDI 580 and PEG 200

582 *I stage.* In a 1 dm<sup>3</sup> jacketed glass reactor fitted with reflux  
 583 condenser, stirrer and nitrogen inlet tube TDI (348.34 g,  
 584 2 M) and benzoyl chloride (1.05 g, 0.3 wt%) was charged.  
 585 After heating the reaction mixture to 65 ± 1 °C, PEG 200  
 586 (100,00 g, 0.5 M) was added drop by drop in 30 min. Then,  
 587 heating was continued 2 h in order to supply total glycol  
 588 conversion. At the end of the reaction, liquid product (I-  
 589 200a) was extracted by the mixture *n*-hexane and ethyl  
 590 acetate equal 2:1. At the end of extraction, the rest of the  
 591 product (I-200b) was evaporated under vacuum. The  
 592 concentration of –NCO groups after the completion of  
 593 extraction amounts to 27.06% (theoretically: 31.76%).

594 *II stage.* In a 1 dm<sup>3</sup> jacketed glass reactor PEG 200  
 595 (372.88 g, 1.86 M) and benzoyl chloride (0.9 g, 0.3 wt% to  
 596 I-200b). After heating the reaction mixture to 65 ± 1 °C,  
 597 300.00 g (0.47 M) I-200b was added in 30 min. Then, the  
 598 heating was continued for 2 h. The obtained product was in  
 599 a form of sticky liquid. Unreacted excess of PEG 200 was  
 600 extracted by toluene. The extraction was carried out to  
 601 getting the weight of sample as theoretical one (486.44 g,  
 602 0.47 M). At the end of the extraction, the rest of toluene was  
 603 evaporated under vacuum. The product (II-200b) was  
 604 obtained in the form of sticky liquid.

605 *III and V stage.* Analogous to the I stage.

606 *IV stage.* Analogous to the II stage.

### 608 3.5. Analytical methods

610 *Concentration of NCO groups.* The typical dibutylamine  
 611 method was employed. Excess of unreacted dibutylamine  
 612 was titrated with aqueous HCl against bromophenol blue  
 613 [19].

614 *Viscosity measurements.* Dynamic viscosity of oligomers  
 615 A<sub>n</sub>B<sub>m</sub> was determined at 25 °C with the use of a rotational  
 616 Rheotest 2 viscometer (Rheotest GmbH). Cylinders of H

617 type were used at the revolution range of 3b to 12a (range I),  
 618 depending on the type of product. No dependence of  
 619 viscosity on shear rate was observed in practice.

620 *Structural analysis.* IR spectra were recorded on a  
 621 Spekord M60 apparatus (Zeiss, Germany). The samples  
 622 were in the form of a thin film on polyethylene substrate.

623 *Mass spectrometry (MS).* The mass spectra of the  
 624 resulting polyurethane oligomers were recorded on an  
 625 electrospray ionisation spectrometer (ESI MS) Finnigan  
 626 MAT 95S (Germany) and on a MALDI MS spectrometer.  
 627 ESI spectra were obtained by using KJ solution for  
 628 ionisation. The mobile phase (CH<sub>3</sub>OH + THF) flow rate  
 629 was set up at 5 μdm<sup>3</sup>/min. Only the positive ions were  
 630 recorded in the range of 200–2000 *M/z*; their molecular  
 631 weight specifications were enlarged by the mass of K<sup>+</sup> (39)  
 632 or Na<sup>+</sup> (22) originating essentially from impurities. The  
 633 samples were diluted with methanol to the concentration of  
 634 pmol/dm<sup>3</sup>.

635 MALDI spectra were recorded on a Voyager-Elite  
 636 (Perseptive Biosystems, USA) apparatus in linear mode  
 637 with delayed ion extraction. The instrument was equipped  
 638 with N<sub>2</sub> laser (337 nm) and the matrix was 2,5-dihydroxy-  
 639 benzoic acid (DHB, *M* = 153 g/mol) dissolved in THF  
 640 (10 mg/cm<sup>3</sup>). The samples were also dissolved in THF (to  
 641 concentration of 1 mg/cm<sup>3</sup>) and NaI in acetone (10 mg/cm<sup>3</sup>)  
 642 was added. The ions with the mass increased by molecular  
 643 weights of Na or K were recorded.

644 *Gel permeation chromatography (GPC).* The GPC  
 645 apparatus used was a Viscotec T60A equipped with a triple  
 646 detector: RI, light scattering (LS) and viscosity detector  
 647 (DV). Separations were made at 30 ± 0.1 °C on a GMH<sub>HR</sub>L  
 648 column (size 7.8 mm × 300 mm) packed with TSK-gel of  
 649 pore diameter 5 μm from Thoso-Haas, and Styragel 1 and 2  
 650 (size 7.8 mm × 300 mm) from Waters. The eluent (THF)  
 651 flow rate was 1 cm<sup>3</sup>/min, volume of inflow circuit—  
 652 20 μdm<sup>3</sup>. Operation of the chromatograph was controlled  
 653 by original computer software *TRISEC Data Acquisition*  
 654 *System* by Viscotec Corporation; deconvolution was  
 655 possible for individual peaks which corresponded to non-  
 656 homogeneous oligomers. The results were interpreted on the  
 657 basis of conventional calibration of columns with carbamate  
 658 standards which had been synthesised especially for that  
 659 purpose. Chromatographic analysis of standards yielded the  
 660 calibration relation for logarithm of mass versus retention  
 661 volume.

$$662 \log M = -0,1595 V_{\text{ret}} + 6.8219 \quad (3)$$

663 The differential curves for distribution of molecular weights  
 664 as obtained from sample elution curves and from the  
 665 calibration equation (3) were presented in the form of  
 666 standardized charts: *detector signal divided by the total area*  
 667 *below the chromatogram - molecular weights of com-*  
 668 *ponents.* The internal standardization method was employed  
 669 to find quantitative compositions of prepolymers from  
 670 thus obtained chromatograms. A special computer software  
 671 Peak Fit v4 was utilised for that purpose which attributed  
 672

Table 2  
Interpretation for GPC chromatograms of monomers and urethane prepolymers

<sup>a</sup> Designations: (1)  $n_i$  ( $i = 2-14$ )—theoretically calculated polymerisation degree (DP) in POG or PCD; (2) A<sub>*n*</sub>B<sub>*n*+1</sub> + 2CH<sub>3</sub>OH—provides the information that the saved file corresponds to the isocyanate prepolymer A<sub>*n*</sub>B<sub>*n*+1</sub> which has been blocked on both sides with methanol (when samples were being prepared for analysis)

non-linear chromatography (NLC) functions to curves after their deconvolution. The obtained results are presented in Table 2.

#### 4. Discussion of results

It was very important for the suggested method that the polyurethane mixture had to be purified carefully, i.e. unreacted diisocyanate and polyol monomers had to be removed therefrom. That can be accomplished by conservative evaporation in vacuum evaporators, what is not so frequently employed in practice, or by means of selective extraction [20]. The latter method was adopted for our work. It was necessary to find selective extraction solvents for every stage of the step-by-step polyaddition process, both for TDI and for hydroxyl monomers. Different polarity specifications of BD, POG and PCD had to be taken into consideration for that process [13].

Extraction was continued until the content of  $-NCO$  groups was obtained which conformed to that calculated theoretically. Fig. 4 shows diagrams for determined concentrations of  $-NCO$  groups in synthesised isocyanate products before and after extraction. The experimental values can be seen close to those calculated from the material balance—excess TDI must have been completely washed away from the products in practice. The presence of unconverted monomers was found to have a strong impact on viscosity of products obtained at successive stages of the polymerisation process: those monomers were masking essential changes in actual viscosities of products which were caused both by the use of polyols with higher and

higher molecular weights, and by the increasing molecular weight of oligourethanes.

It is apparent from Fig. 5 that the effects of those factors can be observed only after monomers have been separated. Viscosity figures for oligourethanes with  $-OH$  terminal groups were found to be higher than those for their isocyanate-terminated analogues and they generally become smaller when polyols used for the reaction have higher molecular weights. The IR spectra confirmed the expected structures of the obtained products.

As results from the examples of IR spectra (Figs. 6 and 7), the structures of oligomers obtained from the same polyols at odd stages (isocyanate prepolymers) and at even stages (urethane–hydroxyl prepolymers) were—as expected—very much similar within individual groups of compounds. Hence, the most essential differences should result solely from the sizes of molecules of individual oligomers. The band at about  $2272\text{ cm}^{-1}$  which represents asymmetrical stretching vibrations of  $-NCO$  groups is the most specific band for isocyanates and it can be observed in case of isocyanate oligomers  $A_nB_{n+1}$  only. On the other hand, the band for stretching vibrations of  $-OH$  groups at  $3450\text{ cm}^{-1}$  appears only in spectra obtained for hydroxyl oligomers  $A_{n+1}B_n$ . When the molecular weight of an oligomer increases, absorption intensity decreases for both these bands, while higher intensities are observed for the amide I band (at  $1730\text{ cm}^{-1}$ ) and amide II band (at  $1536\text{ cm}^{-1}$ ). The former is shifted towards lower frequency values which proves the presence of hydrogen bonds, and the latter represents the combination of scissoring vibrations in  $-N-H$  and stretching vibrations in  $-C-N$  groups [21, 22].

No band was found at  $2130\text{ cm}^{-1}$  in IR spectra which

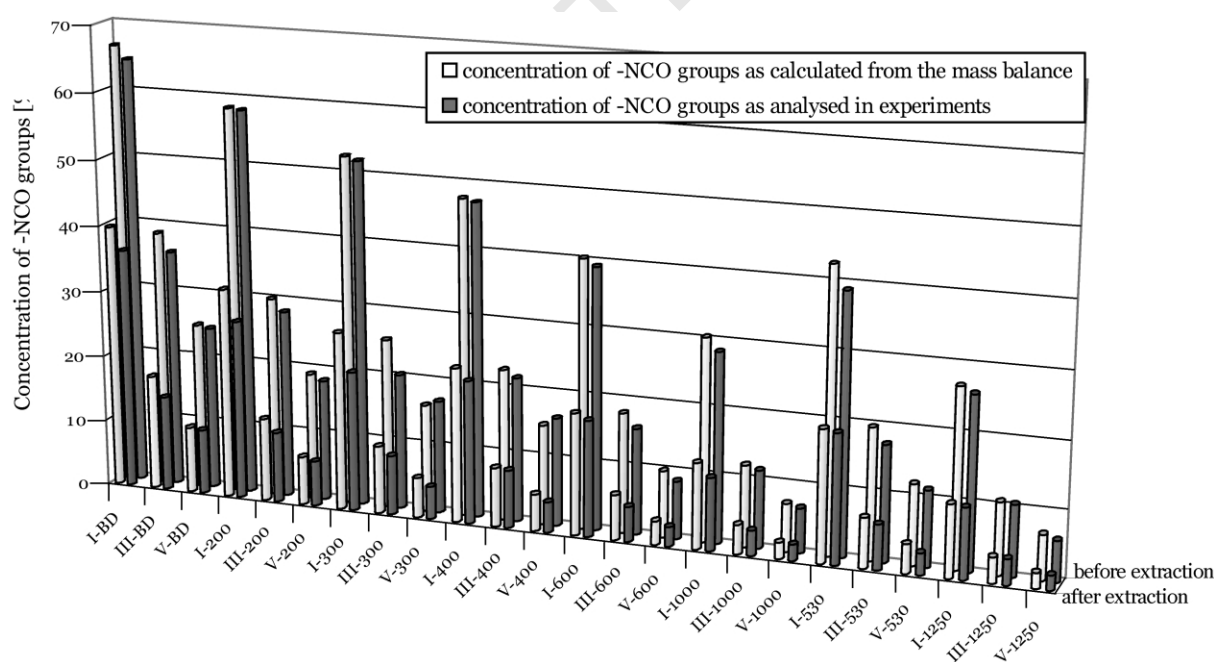

Fig. 4. Determined concentrations of free  $-NCO$  groups in prepolymers against the values calculated from mass balances.

Fig. 5. Viscosities of obtained urethane oligomers before and after extraction.

could represent carbodiimides, and a wide band was observed at  $1695\text{--}1755\text{ cm}^{-1}$  (max. at  $1725\text{--}1730\text{ cm}^{-1}$ ) which in theory could represent urethidiones formed during dimerisation of isocyanates. On the other hand, the band at  $1410\text{ cm}^{-1}$ , which is attributed to isocyanurates, appears in some spectra only and its signal is not very high. Thus, one can infer that only some small amount of excess isocyanates has been converted to undesirable by-products. That is essential for the concept of the whole study as it confirms that the conditions adopted for the synthesis have made it possible to obtain generally linear urethane oligomers with

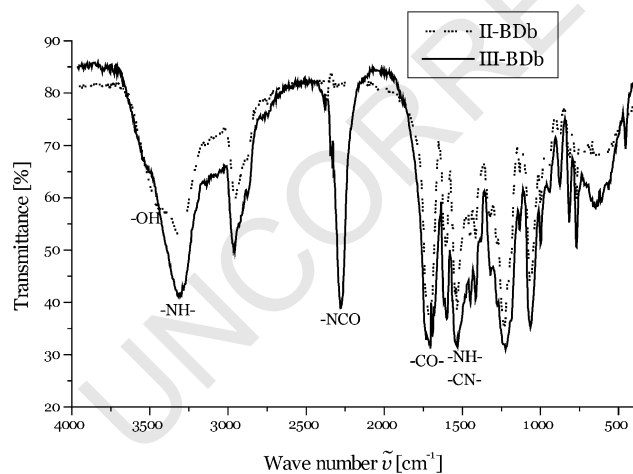

Fig. 6. IR spectra of isocyanate oligomer and hydroxyl oligomer obtained from the second and third stages of the reaction of butan-1,4-diol and TDI (II-BD b and III-BD b as per Table 1).

–NCO terminal groups, even at a relatively high excess of the isocyanate monomer [23].

Confirmation of chemical structures of urethane oligomer chains (Table 2) made the first step towards learning complete compositions of synthesised polymers. Following the idea of scheme (2), PUs obtained at successive stages of the polyaddition process should be initially mixtures of monomers and oligomers, and after extraction—mixtures of predominantly oligourethanes, and it is necessary to identify individual components. This problem was solved by analysing individual samples with the use of size exclusion chromatography (GPC) as well as mass spectrometry (ESI and MALDI-TOF) methods in which mild excitation techniques were employed to take records of basic

Fig. 7. IR spectra of isocyanate oligomer and hydroxyl oligomer obtained from the first and second stages of the reaction of PCD-530 and TDI (I-530 and II-530 as per Table 1).

molecular ions. It was possible from GPC chromatograms which were recorded with the use of three detectors: RI, LS and DV, to obtain a reasonably precise function of molecular weight distribution (MWD) for individual samples of studied oligomers and to make their quantitative evaluation (Table 2).

The obtained data were correlated with the figures calculated from the mass balance for individual steps in the synthesis. It is obvious that the basic reason for polydispersity of every urethane oligomer sample is primarily polydispersity of the hydroxyl component itself. All diols, except for BD, were inhomogeneous materials as regards their chemical compositions. Hence, adequate polymerisation degrees  $n_i$  were required to be attributed to every component (i.e. to every peak) in chromatograms of POG or PCD. Then, in order to be able to compare homogeneity features of oligourethanes produced at successive polyaddition stages, the Peak Fit v4. software was employed to calculate the corresponding MWD curves. The exemplary charts are shown in Figs. 8–10.

The adopted procedure made it possible to observe the step-by-step growth of molecular weights of oligomers produced at every step of polymerisation. The best chromatographic separation was obtained for samples taken from the reactor just after step 1 and step 2, when the chemical composition of the mixture analysed was reasonably simple. Good separation was then harder and harder to achieve as the mean molecular weights of products increased. The obtained MWD curves—especially for stage 5 and stage 6—became similar to those described in reports for high-molecular-weight PUs synthesised for example of ethylene glycol polyadipate, TDI or MDI and then expanded with ethylene glycol [24].

One dominant oligourethane is usually observed in the polymer mixtures after the first two stages; its structure results from adopted stoichiometry (Table 1). The chemical compositions of products obtained from further stages become much more complex and adopted stoichiometry is

decisive more for the types of terminal functional groups rather than for reaction selectivity. In parallel to the most welcome oligomer, there are always a few other products present and their shares happen to be comparable to that of the required product. Some small amounts of high-molecular-weight products appear as early as at the initial two steps. For example, step 1 will yield  $A_1B_2$  but also isocyanate oligourethanes with higher molecular weights ( $A_2B_3$  and  $A_3B_4$ ) will be produced. Unconverted monomers can also be observed in some samples.

Further polymerisation steps produce compounds with higher molecular weights, as expected, but they also yield lower oligomers, probably by the reaction of monomers introduced with monomers which have not been completely removed from previously synthesised products.

The recorded chromatograms made the basis for the calculations of number average ( $\bar{M}_n$ ) and weight average ( $\bar{M}_w$ ) molecular weights as well as polydispersity degrees  $PD = \bar{M}_w/\bar{M}_n$  for the products formed. The values for the latter fall within 1.05–2.37 and they tend to be even closer to the scope of 1.1–1.3. No distinct increase in the scatter of molecular weights could be observed along the sequence of polyaddition stages—that is advantageous for the process offered. The values of  $PD > 1.3$  are specific for oligourethanes in which some amounts of monomers can be found after they have not been extracted out completely, and in particular for isocyanate prepolymers in which some small amounts of TDI are present.

The ESI and MALDI-TOF mass spectrometry methods were employed to unambiguously identify individual compounds within the analysed samples which had been found present on the basis of SEC analyses. The bands are visible in recorded MS spectra which can be attributed to the suggested molecular ions of oligomers, i.e. their sizes and structures, with the atomic weights of  $Na^+$ ,  $K^+$  or  $H^+$  cations added, as results from the adopted excitation method. Majority of positive ions present in ESI spectra contain K which has been introduced as KJ, and some minor

Fig. 8. MWD curves for oligomers (I–V) BDd (Table 2).

Fig. 9. MWD curves for oligomers (I–V) 200b (Table 2).

part of them contain Na. MALDI-TOF spectra principally take records of adducts of oligomers and  $\text{Na}^+$  or  $\text{H}^+$  cations, and also possibly of  $\text{K}^+$  (about 15%) [1,2]. Additionally, isocyanate products reacted with methanol employed to dissolve samples which is also apparent in our findings.

The recorded spectra reveal generally a high number of  $M/z$  signals with much diversified intensities; after a detailed analysis, we managed to make signal-product pairs for majority of expected adducts. Theoretically calculated molecular weights of polyols and urethane oligomers match with the locations of their corresponding signals in MS spectra. Every spectrum has been made up of a specific sequence of signals arranged at the intervals of  $M/z = 44$  from each other, that corresponds to the structural unit of  $-\text{CH}_2\text{CH}_2\text{O}-$  for POG, or at the intervals of  $M/z = 114$  (i.e.  $-\text{CO}(\text{CH}_2)_5\text{O}-$ ) for PCD (Table 3).

The ESI spectra can take records of MWD only up to the value of  $M/z = 1200$ . Hence, it was impossible to fully identify the components of the samples studied (Figs. 11 and 12) [25,26]. Additional information on the chemical

compositions of the investigated oligomers could be obtained by comparing ESI spectra to GPC findings.

The MALDI-TOF technique is capable of analysing a much broader scope of  $M/z$ . Just for illustration, Figs. 13 and 14 show exemplary spectra for oligomers obtained from two stages of reactions of TDI and POG 300, while the detailed interpretation of spectra for all the synthesised oligomers have been shown in Table 3.

The employed MS methods complement the chemical compositions of oligomers as found by GPC and make them reliable. Said compositions are much more complex than one could expect from the balance calculations and from kinetic modelling, still the general compatibility with the model has been kept. In the MS spectra recorded, signals can be seen, which represent, for example, oligourethanes created from POG or PCD molecules with various polymerisation degrees  $n_1$ . When individual molecular ions are precisely recorded with the use of MALDI-TOF technique, the compounds, which could not be isolated with the GPC method due to poor separation of individual

components, even with the use of three chromatographic columns connected in parallel, can be identified. Some MS spectra reveal the presence of oligomers with the compositions close to expectations, which seemed to be ‘missing’ in GPC, while some other spectra demonstrate many more high-molecular-weight products which have been recorded in chromatograms in the form of so-called ‘tails’.

We also made attempts to correlate the findings from quantitative determinations with the data obtained from mass balances for the reactions (Table 1). It was assumed for the qualitative evaluation of chromatograms that the peak areas were representative for concentrations of the components, and the linear performance profile was also assumed for the RI detector. The values of  $dn/dc$  for monomers are in fact lower than those for oligomers, and hence the concentrations calculated for the former could be overestimated [27,28]. Deviations from  $dn/dc$  for oligomers higher than tetramers were assumed to be negligible and thus the detector signals to be proportional to concen-

Fig. 12. ESI spectrum for oligourethane II-200b. (Table 3).

trations. Deconvolution of poorly separated peaks was necessary for quantitative measurements by the internal standardization method, what was possible with the use of the computer software.

The results calculated theoretically and the findings from the GPC method are compared in Table 2. Good correlation can, in most cases, be observed for those two sets of data. The differences result from the fact that not only the principal oligomer—at the highest volume—is recorded in GPC chromatograms and MS spectra. Other high-molecular-weight products have also been observed and their volumes are much higher than those obtained from the balance. Moreover, chromatograms prove the presence of some amounts of unconverted monomers and oligomers with lower molecular weights, what could not be taken into consideration for theoretical calculations. Hence, the findings from the SEC analyses can be slightly overstated in relation to actual values.

## 5. Conclusions

As comes from the literature reports, developing new methods of synthesis for isocyanate and hydroxyl intermediates can be found useful for the manufacturing processes capable of yielding, for example, new types of elastomers, coatings and aqueous emulsions of PUs. The two-stage bulk polyaddition process of diisocyanates and polyols, which is most frequently employed, will not produce any well-defined and regular segmented structure. This is most probably not only because of chain irregularities (imperfection) but also due to considerable polydispersity of chemical composition and MWD of thus obtained linear PUs. That is typical for the equilibrium polymerisation process in which many molecules are present at every moment in the reaction system—basically monomers at the beginning, and then oligourethanes which are progressively produced and which simultaneously decay over time. The need to extend the prepolymer chains afterwards with the use of low-molecular-weight compounds makes the composition of the polyurethane mixture even more complicated. It is, hence, justified to develop a method which can give us all a tool to much better control the structure and that means to control the properties of polyurethanes.

The computer simulation based on the kinetic model for the step-by-step polyaddition process was found useful in developing grounds for the polyaddition process capable of yielding linear urethane oligomers with  $-OH$  and  $-NCO$  terminal groups and narrow MWDs. Our studies proved that those products could be obtained in a multi-staged polyaddition process of 2,4-TDI and 2,6-TDI with various hydroxyl compounds: low-molecular-weight diol (BD), polyethers (POG) or polyesters (PCD), with the excessive amount of one reacting substance employed. These reactions can be carried out in bulk, with no external catalyst, in

Fig. 13. MALDI-TOF spectrum for oligourethane I-300b (Table 3).

the presence of benzoyl chloride which stabilises urethane–isocyanate prepolymers produced. However, it is necessary to separate excess amounts of monomers after every process stage—that can be done by means of selective extraction methods.

The structural studies involved the GPC as well as IR, ESI and MALDI-TOF spectrometry methods and they could identify all intermediates—urethane oligomers which were progressively produced and which simultaneously decayed in the step-by-step polymerisation process. Chemical structures of oligourethanes obtained from the same polyols

at odd stages (isocyanate prepolymers) and at even stages (urethane–hydroxyl prepolymers) were—as expected—much similar within particular groups of compounds, and the essential differences refer to the molecular sizes of oligomers. The presence of unconverted monomers clearly affects the viscosity specifications of the products obtained from downstream stages of the polymerisation process. After thorough purification of products, said viscosity is dependent on molecular weight of polyol employed in the reaction and on the process stage which yielded the product in question.

Fig. 14. MALDI-TOF spectrum for oligourethane V-300b (Table 3).

2801 One dominant oligourethane is usually observed in the  
 2802 polymer mixture obtained after the first two polyaddition  
 2803 stages. Its structure is determined by the adopted stoichi-  
 2804 ometry. Chemical compositions of products from further  
 2805 stages become much more complex. Hence, the stoichiometric  
 2806 ratio is rather decisive for the type of terminal functional  
 2807 groups than for the reaction selectivity. The expected oligomer  
 2808 is always accompanied by a few other products which can be  
 2809 present even at comparable concentrations. It happens  
 2810 frequently that some small amounts of high-molecular-weight  
 2811 products appear as early as at the initial two stages of the  
 2812 process. These compound, however, always have identical  
 2813 end groups: –NCO or –OH.

2857 It is possible to restrain the polydispersity degrees for the  
 2858 obtained oligomers to the range of 1.1–1.3, and—what is  
 2859 significant—no clear increase in MWD is observed with the  
 2860 progress of the polyaddition stage.

2861 The findings for –NCO group contents and quantitative  
 2862 determinations with the GPC method confirmed the general  
 2863 consistence of expected chemical compositions of oligo-  
 2864 mers and the data calculated on the basis of mass balances  
 2865 for individual process stages.

2866 Since excessive amounts of one of monomers need to be  
 2867 separated after every process stage, this method is  
 2868 applicable for semi-commercial plants of big laboratory  
 2869 stands to produce oligourethanes with precisely defined

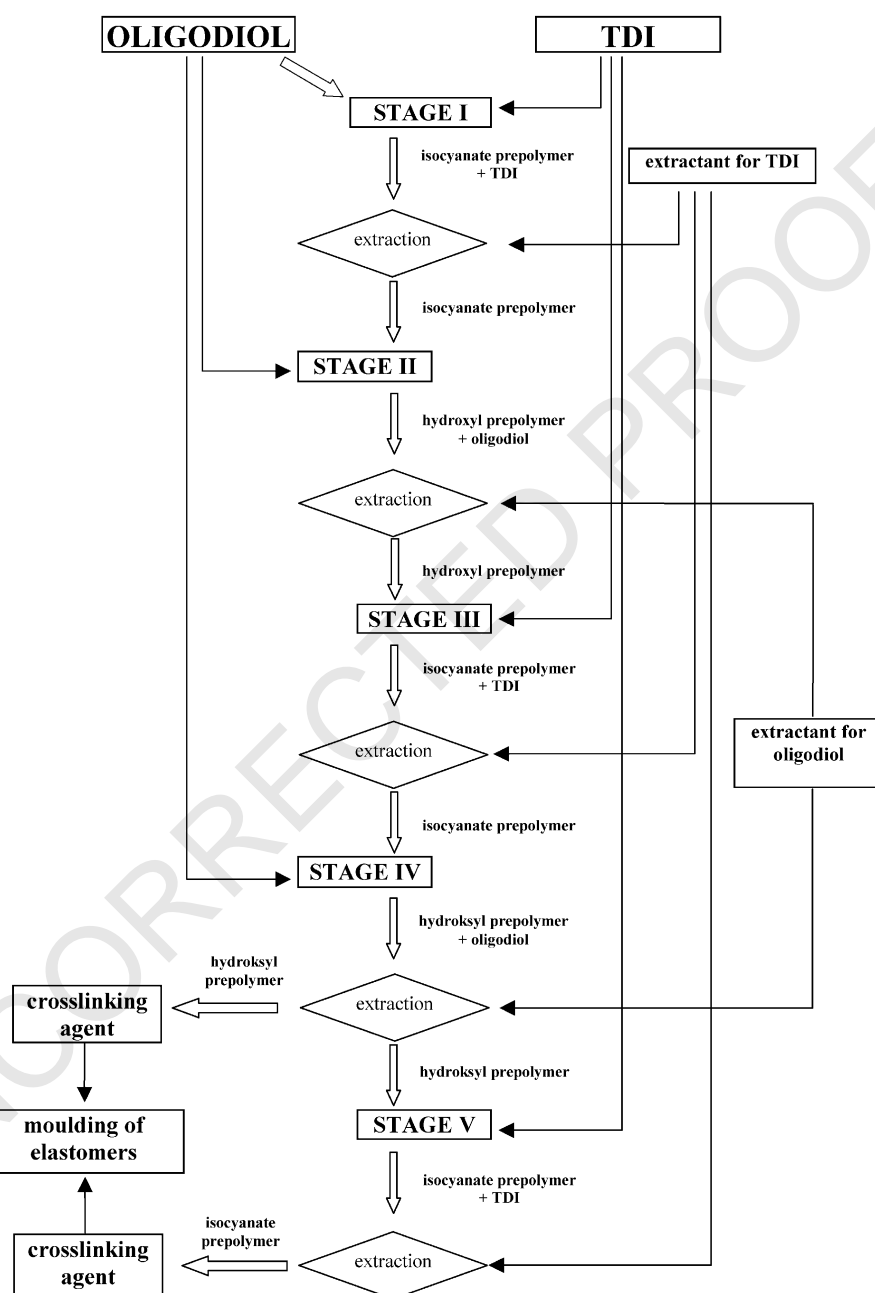

Fig. 15. Flow diagram for the process which yields polyurethanes with controlled molecular weights.

2913 chemical compositions and regular chain structures. Such  
 2914 products can then be further processed, i.e. expanded to  
 2915 form linear polyurethanes with narrow MWDs and sub-  
 2916 jected to cross-linking, to yield foamed plastics or  
 2917 elastomers, e.g. with the RIM technique, or they can be  
 2918 used as macro-urethane cores on which chains of vinyl  
 2919 polymers can be grafted. The future process arrangement(s)  
 2920 must recycle separated monomers to the loop. The idea of  
 2921 such a process was presented in a diagram (Fig. 15) [29].

2922 Then, it will be necessary to reveal the effect(s) of  
 2923 chemical structures of PUs synthesised from oligourethanes  
 2924 presented herein on supermolecular structures and thermal–  
 2925 mechanical properties of those PUs against PUs synthesised  
 2926 from the same feedstocks but in a single-stage method.
